Summary

A total of 348 serum samples were collected from 301 hemodialysis patients with chronic renal failure of four healthcare settings in Western Bohemia. The sera were screened for the presence of hantavirus antibodies using ELISA kits (PROGEN Biotechnik GmbH) with Hantaan and Puumala antigens. Specific anti-Puumala antibodies were detected in five patients (1.7 %). Although hantaviruses are known to cause primarily acute renal damage (interstitial nephritis) in Eurasia, chronic effects of hantavirus infection and the detection of specific antibodies in hemodialysis patients have also been reported. Nonetheless, the detection of seropositivity is not proof of an etiological link between hantaviruses and chronic renal failure. The hantavirus seropositivity rate in hemodialysis patients was not significantly higher than that in the general population. Our findings are consistent with the literature data and do not contradict the contribution of hantaviruses to the pathogenesis of chronic renal damage in the Czech Republic.

Key words: hantaviruses – hemodialysis patients – nephritis – antibodies – Czech Republic.

Souhrn

Pejčoch, M., Pazdiora, P., Eiselt, J., Hájek, V., Veselá, E., Vlasák, J., Benešová, J., Kubátová, A., Kříž, B.: Prevalence hantavirových protilátek v sérech hemodialyzovaných chronických pacientů v České republice

Bylo odebráno 348 vzorků sér 301 hemodialyzovaným pacientům trpícím chronickým selháním ledvin v čtyřech zdravotnických zařízeních v Západočeském kraji. Séra byla vyšetřena na přítomnost hantavirových protilátek pomocí ELISA soupravy (PROGEN Biotechnik GmbH) s antigeny viru Hantaan a Puumala.

Specifické protilátky proti antigenu viru PUUMALA byly detekovány u pěti pacientů (1.7%). I když je známo, že hantaviry v Eurasii vyvolávají především primární poškození ledvin (intersticiální nefritidu), chronické následky hantavirových infekcí a detekce specifických protilátek u hemodialyzovaných pacientů byly hlášeny také. Nicméně zjištění séropozitivity se nepovažuje za průkaz etiologické souvislosti mezi hantaviry a chronickým selháním ledvin. Podíl hantavirové séropozitivity u hemodialyzovaných pacientů není signifikantně vyšší než u celkové populace. Naše nálezy souhlasí s údaji v literatuře a nejsou v rozporu se zjištěním, že se hantaviry mohou podílet na patogenezi chronického poškození ledvin v České republice.

Klíčová slova: hantaviry – hemodialyzovaní pacienti – nefritida, protilátky – Česká republika.

Introduction

Diseases caused by hantaviruses are not yet well known in Central Europe and thus may escape detection or be misdiagnosed. Despite this fact several attempts have been made to assess and clarify epidemiological, microbiological and social features of this disease [14, 15, 17]. They are classified in the group of emerging infections. Although the diseases caused by hantaviruses have been known for a long time, the causative agent was not identified until 1976. In 1978, the Korean scientist Ho Wang Lee described the causative agent of Korean hemorrhagic fever and named it after the Hantaan river where he first isolated the virus [3]. The genus Hantavirus was newly recognized in the family *Bunyaviridae*. Hantaviruses are negative-sense single-stranded RNA viruses. Over 30 hantavirus species are currently known.

In nature, hantaviruses circulate among their specific rodent hosts. As a result of co-evolution, each hantavirus genotype has a specific host. Hantaviruses cause persistent asymptomatic infections in rodents, but are also implicated in severe diseases in humans. Rodents excrete hantaviruses in urine, faeces and saliva into the environment. The respiratory tract is the most common route of entry for the hantavirus that is transmitted to humans through the inhalation of contaminated aerosols. In Eurasia, hantaviruses primarily affect the kidney, causing hemorrhagic fever with renal syndrome (HFRS), or its milder form, nephropathia epidemica (NE). The disease results in renal failure that may progress to chronicity. HFRS is a systemic infection. The retroperitoneum is the major site of vascular leak and the kidneys suffer tubular necrosis. Both syndromes are accompanied by myocardial depression and hypotension or shock [9].

The following hantavirus genotypes are circulating in nature in Central Europe: Puumala (PUU) whose host is the bank vole (*Myodes glareolus*), Dobrava-Belgrade (DOB) harboured by the yellow-necked mouse (*Apodemus flavicollis*) and Tula (TUL) circulating among common voles (*Microtus arvalis*). The Hantaan (HTN) genospecies is typically found in Asia but not in Europe. Three genospecies, i.e. PUU, DOB and TUL, have been detected in the Czech Republic [7], with DOB virus posing the highest risk and even causing death in humans (unpublished data). TUL virus can also be responsible for infection in humans, but only one mild case has been reported to date [16].

Hantaviruses are generally considered to cause acute renal damage in Eurasia. Nonetheless,

chronic hantavirus infection has also been reported, even in hemodialysis patients. We decided to screen a group of dialysis patients from Western Bohemia for the presence of specific hantavirus antibodies.

Patients & Methods

Serum samples for laboratory testing of specific hantavirus antibodies were obtained from three healthcare settings in Western Bohemia. A total of 107 serum samples from 1997 and 107 serum samples from 2000 were provided by the serum bank of the Hemodialysis Centre of the Teaching Hospital in Plzeň. The sera were collected from 167 patients, with some of them being sampled repeatedly. Thirty-five sera samples from 2000 were obtained from the EuroCare Centre, Military Hospital Brno. Seventy sera collected from 70 patients in June 2000 were from the NMC Hemodialysis Centre Ltd. in Sokolov. Other 29 sera from July and August 2000 were provided by the Hemodialysis Centre of the Department of Internal Medicine in Klatovy. Thus a total of 301 patients, 150 males and 151 females, male to female ratio 1: 1.01, age range 20-87 years, mean age 61.0 years, were screened. For the patients sampled twice (in 1997 and 2000), the age at the first blood sample collection was taken into account.

The blood samples were stored frozen at a temperature of -20 °C until the analysis. The antibodies were detected by commercial ELISA kits with the Hantaan and Puumala antigens (PROGEN BIOTECHNIK GmbH, Heidelberg, Catalog Nos. PR59065 and PR59056). The Hantaan antigen was used because no commercial kits with the Dobrava antigen have been available on the market, and these two genotypes are closely similar. Therefore, anti-Dobrava antibodies were detected by the kits with the Hantaan antigen. The results were evaluated according to the manufacturer's instructions. To demonstrate the reproducibility of the serology results, some of the sera were examined up to seven times, before the final result was determined. The sera were screened for the presence of specific IgG and IgM antibodies.

Results

The aforementioned kits were used to examine 348 sera from 301 chronic hemodialysis patients. In five (1.7 %) patients, four females and one male, the levels of specific antibodies suggested hantavirus infection. Six patients with borderline levels of antibodies were retested several times to be excluded after failing to give positive results.

Case histories of patients positive for hantavirus antibodies:

Patient No. 1.: A 78-year-old woman who presented with pneumonia and renal failure in 1997. Since October 1997, she had been on dialysis. Diagnosis: nephropathy of unclear etiology with cortical cysts as a cause of renal failure. In 2001, she died of heart failure.

Patient No. 2: A 77-year-old woman, a forest

Table 1. Serology results of five positive patients.

Patient characteristics			Result			
			IgG		IgM	
Patient No.	Sex	Sample from	HTN	PUU	HTN	PUU
1	F	1997	negative	negative	negative	negative
		2000	positive	positive	negative	negative
2	F	1997	negative	negative	negative	positive ¹
		2000	negative	borderline	negative	positive ¹
3	M	1997	negative	positive	negative	negative
		2000	negative	borderline	negative	negative
4	F	1997	negative	positive	negative	positive ²
		2000	negative	borderline	negative	positive ²
5	F	1997	positive	positive	negative	positive

Notes: ¹ Anti-PUU IgM highly positive in 1997 and lower positivity detected in 2000; ² Anti-PUU IgM positive in both 1997 and 2000 at the same level

worker, who had been on dialysis since May 1995. Diagnosis: suspected diabetic nephropathy. She died in 2000.

Patient No. 3: A 44-year-old man who was diagnosed with renal failure of unclear etiology. He has been on dialysis since 1991 after presenting with uremia and signs of chronic renal failure progression. He has chronic viral hepatitis B.

Patient No. 4: A 72-year-old woman who lived in a small house with a garden and worked in a vegetable warehouse with the presence of rodents developed a flu-like illness with fever in 1992. She was diagnosed with impaired renal function and had been on dialysis after worsening of renal function in 1994. The patient died of heart failure in 2002. Signs of glomerulonephritis were found at autopsy.

Patient No. 5: A 73-year-old woman who had been on dialysis since June 1997 for chronic progressive pyelonephritis died in 1999.

Discussion

In Europe, hantavirus primarily affects the kidney and causes a form of HFRS called nephropathia epidemica. The disease usually has an acute course with the following five stages: (i) febrile, (ii) hypotensive, (iii) oliguric, (iv) polyuric, and (v) convalescent. The mortality rate in Europe is low. The patients usually recover completely. Delayed effects or a chronic form of the disease are relatively rare to be reported.

Elisaf et al. have described 32 Greek patients admitted to hospital for hemorrhagic fever with renal syndrome, but gave no details on the causative agents. Two of these patients developed renal dysfunction persistent for more than one year. Three recovered patients were diagnosed with type I distal renal tubular acidosis at 1 to 5 year follow-up and two of them had reduced renal concentration capacity. The development of chronic renal dysfunction was independent of

severity of the initial acute disease [1]. In a Mayo Clinic study, 165 serum samples from patients with acute or chronic renal disease, 34 serum samples from patients with congenital renal disease, and 100 serum samples from healthy adults were tested by EIA for the presence of IgG, IgM and IgA antibodies against Hantaan and Puumala viruses. Specific antibodies were detected in 26 % of patients from the first group, in 3 % of patients with congenital renal disease, and in none of the third group. The positive patients from the first group had the following diagnoses: acute tubulointerstitial nephritis (9 patients), necrotizing glomerulonephritis (12) or IgA nephropathy (9), and other renal disorders (15). IgA, IgG and IgM positivity was found in 37 %, 33 % and in 17 % of cases, respectively. The remaining 13 % of cases were positive for all three types of antibodies [6]. Shutov et al. have reported that some patients with chronic renal failure from the middle Volga river valley had a history of hemorrhagic fever with renal syndrome. They concluded that hemorrhagic fever with renal syndrome contributed to the development of chronic renal failure in endemic areas [11]. Novo et al. have described Puumala virus infection in a 15-year-old boy with severe acute renal failure whose renal function subsequently remained mildly altered for more than two years [5]. Settergren et al. have also reported a persistently reduced glomerular filtration during the convalescence period [10].

There are only scarce literature data available on the prevalence of hantavirus antibodies in hemodialysis patients. Tsianos et al. screened 114 chronic hemodialysis patients (age range 14 to 73 years) for the presence of antibodies against hepatitis C virus and hantaviruses. Hantavirus antibodies were detected in 15 patients (13.2 %). Their presence correlated neither with transfusion nor with time on hemodialysis. It has been recommended to screen hemodialysis patients for the presence of hantavirus antibodies, in particular those with unclear cause of chronic

renal failure [13]. In Israel, the presence of antibodies against Hantaan virus in chronic hemodialysis patients was investigated by Smetana et al. using indirect immunofluorescence. They found IgG antibodies against Hantaan virus in 11.6% of 43 screened patients and in 12.5% of 40 healthy control volunteers. Most of these study subjects originated from Asia and no difference was found in the level of infection between chronic hemodialysis patients and healthy people [12]. In 1990, Grcevska et al. from Skopje, Macedonia, have reported two cases of acute renal damage caused by hantavirus infection, one of which developed chronic renal failure with polyuria [2].

In our group of hemodialysis patients, we detected antibodies against hantaviruses in five of 301 (1.7%) study subjects. Most positives were females (80%). The PUU genotype was the causative agent in all five cases. Data from patient No. 2 showed the dynamics during the examination of serial serum samples. Her levels of anti-PUU IgM antibodies decreased over three years, while IgG antibodies switched from negativity to borderline values. The other patients exhibited a less typical course of infection. It must be noted, however, that hantavirus serology results are often inconclusive [4].

Like others, we detected both IgG and IgM hantavirus antibodies, anti-PUU antibodies in particular, in a proportion of hemodialysis patients. The average antibody prevalence rate in the Czech population is reported to be 0.8% (our unpublished data), and 1.97 [8]. Seroprevalence of hemodialysis patients differs not statistically significantly from the seroprevalence of the population. However involvement of hantaviruses in renal failure could not be excluded. It is obvious that hantaviruses may also contribute to chronic renal damage in the Czech Republic.
